Abstract

We study the problem of maintaining materialized views of graph structured data. The base data consists of records containing identifiers of other records. The data could represent traditional objects (with methods, attributes, and a class hierarchy), but it could also represent a lower level data structure. We define simple views and materialized views for such graph structured data, analyzing options for representing record identity and references in the view. We develop incremental maintenance algorithms for these views, and discuss how to realize these algorithms when only a data warehouse (and not the data sources) knows the view definition.

1 Introduction

Relational views are useful for controlling data access, specifying contents of caches (or remote copies), and other data management tasks. In this paper we study how to extend this view concept and the associated maintenance algorithms to what we call a *graph structured database* (GSDB). Informally, a GSDB is a collection of “objects” that may contain “pointers” (graph edges) to other objects. A GSDB can represent Web pages, Lotus Notes documents, or other semi-structured information; it can also represent graph data structures such as a PERT chart, or a circuit design.

Example 1: Graph structured database

Figure 1 shows a graph structured database. Each node in the graph represents an object, each directed

Figure 1: A graph structured database

edge (pointer) represents a parent-child relationship between two objects. Users can traverse the graph by

starting from an object and following the edges. We assume each object in the graph has an object identifier (OID) and some other fields that we will describe in Section 2. \square

Views on a GSDB can be used for at least two tasks: defining cache contents and query filtering. For example, consider a set of interrelated Web pages. For now, assume that each page is an object, and the URLs in pages are the graph edges. Say that a user is interested in all Web pages containing the word “flower” and would like to copy them to his local disk for faster access. Using the constructs we define in this paper, a user will be able to define a *materialized view* to select the objects (and possibly edges) that should be copied. When the original objects change, the materialized view needs to be updated, and the incremental maintenance algorithm we discuss in Section 4 will keep the view up to date (at least for certain simple types of views).

A view can also be used to “filter” the objects that are accessed by a query. For example, a parent may wish to restrict access by his children to a particular subset of Web pages. For this he can define a *virtual view* (not materialized) that contains the allowed Web pages. Similarly, a user may have identified an interesting set of Web pages, and would like to use this set as a starting point for future queries. Again, a virtual view, defined using the constructs we will present, can be used for this purpose.

The data model we use in this paper is a “lightweight” one, without notions of object classes and inheritance. In particular, in Figure 1, objects A, B, \dots are indistinguishable as far as the system is concerned. We believe that this makes our model more generic and widely applicable (e.g., to Web pages). Furthermore, even if an application requires classes or inheritance, the underlying data will most likely be stored by the database system as a GSDB. For example, the system may identify the class of an object by adding a special system field or tag to each object. (It could also link together all objects in a class.) An object A that inherits from another object B could have a special system pointer to B , for instance. Thus, the same view machinery we discuss in this paper could be used to cache or control access to the underlying data structures used to implement a more structured model.

Even though the notion of a GSDB view is similar to that of a relational view, there are a number of new challenges due to the richer nature of the GSDB model. For example, what exactly is a view on a GSDB? Is it just a collection of objects, or does it also include the edges between the objects? For instance, in Figure 1 say that our view includes the portion of the graph enclosed by the dotted line. Is the edge from B to C officially part of the view? In this case, perhaps a user that is given access to the view should not see the link from B to D . However, it is not clear how to achieve this, since the user could anyway retrieve the contents of B which somewhere contains the C, D pointers. Saying that the view simply contains objects B and C is simpler (no need to track edges), and if the view is materialized, then one could modify the contents of B so that it no longer contains the pointer to D . However, arbitrary “editing” of the materialized objects complicates view maintenance.

In a materialized view there is also the question of object identifiers. In our example, what should the

OID of the copy of B be, and how can we identify the original object? Should the materialized copy of B contain a pointer to object C , or to the copy of C in the materialized view? Whatever the choice for materializing views, there is also the problem of incrementally maintaining them as the original data is modified. This is a much harder problem than for relational views. In particular, if we modify a tuple in a relation, we know that only views defined on that relation may be impacted. In a GSDB, a simple change like adding a link between two pointers can dramatically change the set of objects in a view. (This will become clearer once we discuss how views are defined.) Thus, as we will see, incremental view maintenance is more complex and more expensive for GSDBs. As a matter of fact, it may only be feasible for relatively simple views.

In this paper we address some of these challenges. In particular, our contributions are:

- We formally define the notion of virtual and materialized views for GSDBs (Section 3). With these definitions, the result of a view definition on a GSDB is another GSDB, making it possible to define views on views and to query views in the same way GSDB are queried. (This same property holds for relational views and makes them especially useful.)
- We present a simple language for defining GSDB views, and mechanisms for restricting access to objects “within” a view. (Section 3). We also discuss implementation issues related to querying and materializing GSDB views.
- We present an algorithm for incrementally maintaining simple materialized views (Section 4). The algorithm takes as input a view definition and a sequence of updates to the base data, and propagates the changes to the copied data, querying the base data when necessary.
- We discuss incremental view maintenance in a warehousing environment, where the base data is stored at sources that export change information but are unaware for the view definitions (Section 5). In this case, queries to the base data will be expensive, so we discuss techniques for reducing the query costs.

1.1 Related Work

Our work is based on previous work on materialized view maintenance [GMS93], object technology [Cat94], querying object oriented database [CD92, CCM96, KS95], and semi-structured data models [Suc97, QR UW95]. In the rest of this subsection we specifically compare our GSDB views to relational views and object views defined using object classes.

Most of the incremental view maintenance work focuses on the relational model, for example, [GMS93, BLT86, GL95]. GSDB views are different from relation views in at least three major ways: (1) As mentioned earlier, in a GSDB view there is no schema to constrain changes to a particular “region;” with relational views, on the other hand, changes to a relation only impact views that refer to that relation. (2) In a GSDB view, there are relationships among objects that need to be preserved in the view. (3) View data

may contain pointers and thus “lead access” to base data, those access need to be controlled. Instead of defining incremental view maintenance algorithms for GSDBs, one could instead represent the graph data as relations (e.g., with a relation storing all edges), and then simply use existing relational maintenance algorithms. However, as we discuss in Section 4.4, directly using the relational algorithms on graph data is not very effective.

Most previous research on object views (e.g., [AB91, Ber92, BDK92, Run92]) use object databases with classes. Views are defined by adding and hiding attributes to base classes. In contrast, since there is no class concept in a GSDB, views in a GSDB need to be defined by query expressions (as we do here). Views defined by adding and hiding attributes over a object classes are a subset of possible views defined using path expressions [KKS92, MBW80]. Also, most of the views considered by researchers so far are virtual views. In our work we consider both virtual and materialized views.

There is, nonetheless, some recent work on materialized object views by the *MultiView* group at University of Michigan [KR95, Run92]. The major difference between their approach and ours is that first, they use the class notion of object databases and define views as virtual classes. As a consequence, the view maintenance problem for them reduced to deciding whether a modified object belongs to a certain virtual class. Second, in their system, each real value (attribute value or method of an object) has only a single physical copy. A materialized view in their system stores only OIDs (pointers) to the real base value, essentially, the view is not a “stand alone” entity that is meaningful without the base objects. So their view maintenance algorithms do not need to worry about duplicating or propagating values of updated objects. However, with their approach the performance advantage of querying materialized views is reduced because each access to an object in a materialized view is decomposed into several accesses to the “real data”. For the same reason, their approach is difficult to adapt to a distributed environment. On the contrary, the materialized views we design in this paper have the ability to duplicate both object pointers and values, and are able to independently maintain the relationship between an object and its duplicate.

Another work that is related to this paper is the view maintenance methods proposed in [Suc96]. Their data model is edge-labeled trees without OIDs, which is similar to our model but syntactically totally different. They use a query language UnQL [BDHS96] to define their views, and use an algebraic approach to maintain the views. That is, they find expressions that can compute delta views corresponding to the changes of base data. However, their approach takes advantage of their language specific constructs, such as tree concatenation, expansion, object markers, and the operator $++$. The UnQL language together with those operators needs to be implemented before one can do view maintenance. Also, their approach only works for views that are defined using “join free” queries, and updates that are either concatenation or replacement of two disjointed graphs. In their case, a view is always self-maintainable. We took a different approach by defining our views using an extension of OQL [Cat94] and designing incremental view maintenance algorithms using common insertion, deletion and update operations. Views defined in this paper can not generally be handled by techniques discussed in [Suc96].

2 Data model

In this section we introduce our object and database model. For objects, we use the OEM model [PGMW95]. Each *object* contains four fields: an OID, a label, a type and a value. The OID of an object is a universally unique identifier. The label is a string that explains the meaning of the object and does not need to be unique. Each object either has an *atomic* type, such as integer or string, or has a *set* type. The value of a set object is a set of OIDs of other objects. The following example shows a collection of objects.

Example 2: A collection of database objects

We enclose each object within a pair of angle brackets and show the OID, label, type and value fields in order.¹ We use indentation as a visual aid to show the hierarchical relationship of the objects.

```
< ROOT, person, set, {P1,P2,P3,P4} >
  < P1, professor, set, {N1, A1, S1, P3} >
    < N1, name, string, 'John' >
    < A1, age, integer, 45 >
    < S1, salary, dollar, $100,000 >
    < P3, student, set, {N3, A3, M3} >
      < N3, name, string, 'John' >
      < A3, age, integer, 20 >
      < M3, major, string, 'education' >
  < P2, professor, set, {N2, S2} >
    < N2, name, string, 'Sally' >
    < ADD2, address, string, 'Palo Alto' >
  < P4, secretary, set, {N4, A4} >
    < N4, name, string, 'Tom' >
    < A4, age, integer, 40 >
```

In this database, object **ROOT** (we refer to an object by its OID) is an example of a *set* object. It has four children objects representing two professors (i.e., with those labels), one student and one secretary. Notice that the subobjects of one professor are structured differently from those of the other professor. Object **A1** is an example of an atomic object. We use $label(O)$ to refer to the label of object O and use $value(O)$ to refer to O 's value. For example, $label(P2) = \text{professor}$ and $value(P2) = \{N2, S2\}$.

This set of objects can also be represented by the graph in Figure 2. For an atomic object, we omit the type since it can be inferred by its value. For a set object, we show the OID and label within brackets, and show its value by outgoing edges. □

Next we introduce the notion of a database in this data model. A *graph-structured database (GSDB)* is an object whose set value contains the OIDs of all objects in this database. Thus, a database is simply a way to group objects together. Objects can be grouped into a database for various reasons, for example, because they are semantically related, they are frequently accessed together, or they are physically located at the same site. If all the objects in Example 2 compose a database **PERSON**, then the object **PERSON** is:

¹In our examples we try to use meaningful OIDs; in general, they can be arbitrary.

Figure 2: A graph structured database

`<PERSON, database, set, {ROOT, P1, P2, P3, N1, A1, S1, N2, ADD2, N3, A3, M3, P4, N4, A4}>`

Notice that a database object is not a special type of object; it is simply a conceptual aid and will be helpful when we discuss views. A database object can have any type of label.

We have selected this particular data model because it is simple, and yet will let us study the important view management issues. Furthermore, we believe that the model and the algorithms we will present easily generalize to other models. For example, objects with multiple fields can be represented in our model by several objects. For instance, a multi-field employee object `< name: 'Joe', salary: 50k >` can be represented as

```

< E1, employee, set, {N1, S1} >
  < N1, name, string, 'Joe' >
  < S1, salary, dollars, 50k >

```

As another example, fixed format records can be represented in our model by repeating the field names (as labels) in each object. For instance, say that a schema defines the first field of a record to be a name and the second field to be a salary. Then the record `< 'Joe', 50k >` can be represented by the same object above. As a third example, some graph structured data models (e.g., [BDHS96],[QRUW95]) have values or labels on edges. These models can be mapped to ours [BDHS96].

Incidentally, note that our model is a conceptual one. The actual implementation could differ. For example, the OID field may not be stored in the record, and could be inferred from the record's location on disk. Repeated labels or values could be compressed in various ways. The database objects we defined may or may not be physical objects; for instance, objects in a database could simply be those contained in a particular region of a disk.

We now define some GSDB terminology that will be used in this paper. A *path* is a sequence of zero or more object labels separated by dots: $p = l_1.l_2 \dots l_n$. For example, `professor.student` is a path. We use $N.p$ to denote the set of objects that can be reached following path p from object with OID N . If $N_2 \in N_1.p$,

then N_1 is an *ancestor* of N_2 , and N_2 is a *descendent* of N_1 . In this case, the first label in p is the label of one of N_1 's direct children, and the last label in p is the label of N_2 . If $N_2 \in N_1.p_1$ and $N_3 \in N_2.p_2$, then $N_3 \in N_1.p_1.p_2$. In the Figure 2 example, node **A1** is a descendent of **ROOT** and can be reached from node **ROOT** following path **professor.age**, that is, $A1 \in \text{ROOT.professor.age}$.²

A *path expression* is a regular expression of paths. For example, $*$, *professor.** and *professor.?* are path expressions. A path is also a (constant) path expression. We say that a path p is an *instance* of path expression e if the wild cards in e can be substituted by paths to obtain p . For any path expression e , we define $N.e$ to be the union of all objects in $N.p$ for all instances p of e .

We allow set operations on objects of type set. In particular, let $S1$ and $S2$ be two set objects. We define $\text{union}(S1, S2)$ to be an object whose value is $\{\text{value}(S1) \cup \text{value}(S2)\}$, and define $\text{int}(S1, S2)$ to be an object whose value is $\{\text{value}(S1) \cap \text{value}(S2)\}$. We assume that these resulting objects have an arbitrary unique OID and take on the label of $S1$ ³. These operations are mainly used to manipulate database objects and query answers, although they could apply to any set objects.

Many languages have been proposed for querying object-oriented databases [KKS92, BDHS96, Cat94, QRUW95, AQM⁺96]. Here we use a simple but representative language that lets us study view management issues. Its basic syntax is:

SELECT	OBJ.sel_path_exp X	(2.1)
WHERE	cond(X.cond_path_exp)	
[WITHIN	DB1]	
[ANS_INT	DB2]	

A query answer is also an object, with the format $\langle \text{ANS}, \text{answer}, \text{set}, \text{value}(\text{ANS}) \rangle$, where $\text{value}(\text{ANS})$ is a set of OIDs. To evaluate the above query without the last two optional clauses, the system considers all objects in OBJ.sel_path_exp . For each object X in this set, the system checks if it satisfies condition $\text{cond}(X.\text{cond_path_exp})$. Boolean function $\text{cond}()$ accepts a set of atomic objects, and returns *true* if one of those object values satisfy the condition. When the condition is true, X is placed in $\text{value}(\text{ANS})$. For example, the query `SELECT ROOT.professor X WHERE X.age > 40` will return $\langle \text{ANS}, \text{answer}, \text{set}, \{P1\} \rangle$ as answer. To write a query, the user must provide an entry point(OID) like **ROOT**. This entry point could be obtained from a previous query, or it could somehow be known to the user. A database name **DB** can also be used as the entry point. Using **DB.?** means that the search starts at all objects in **DB**.

Notice that the above query can span multiple databases. In Example 2, say that all objects are in database **D1** except for **A1** which is in database **D2**. In this case **P1** points to a “remote” object. The query `SELECT ROOT.professor X WHERE X.age > 40` will still return the same answer, since the query is insensitive to the “location” of objects. (Contrast this to relational queries where the relation a tuple belongs to is important.) The two optional clauses we now define attempt to control the “scope” of a query. As far

²We use the terms node and object interchangeably.

³Typically set operations are only meaningful when objects $S1$ and $S2$ has the same label.

as we know these clauses are not part of traditional object-oriented query languages, but as we will see, they will be useful for posing queries on views.

The `WITHIN DB1` clause limits the search to a single database `DB1`. The effect is that any OIDs that are not in `DB1` are completely ignored by the query. For our example where all nodes are in `D1` except `A1`, then our sample query with the clause `WITHIN D1` will have an empty result.

The clause `ANS_INT DB2` specifies that the answer object should be intersected with the `DB2` object to yield the final answer. This means that the answer objects are constrained to be in `DB2`, but the evaluation of the `WHERE` clause can follow remote pointers. For the example in Figure 2, if all nodes are in `D1` except `A1`, then the query with `ANS_INT D1` will return `<ANS, answer, set, {P1}>`. However, if all nodes except `P1` are in `D1`, the same query will return an empty set. The `ANS_INT` clause is mainly used to restrict a query answer to objects within a certain database. As we will see in the next section, we can use this clause to restrict user queries to return only objects within certain views.

Finally, we want to stress that we have selected a simple language, not because other features are not useful, but because these other features are not necessary for discussing simple view management. Features such as `FROM` clauses (e.g., in OQL [Cat94] or Lorel [AQM⁺96]), multiple paths in `SELECT` clauses, or multiple conditions in `WHERE` clauses could easily be added to our language. However, some of these features would make incremental view management (Section 4) substantially more complex.

3 Views and materialized views

A *view* is a set of imaginary objects defined in a precise way from real objects [Ull88]. A view can be used to hide or restructure objects from the underlying database. A view can also be used to specify what objects to cache for performance reasons.

As discussed in Section 1, defining views on GSDBs introduces some challenging problems regarding the structure of a view, how it can control access, and how it can be materialized. However, now that we have defined query answers to be the same as databases, we can think of views as other databases, available for querying. However, the situation is still different from a relational context because a query answer simply contains a set of OIDs that are not meaningful without the original data. In a relational view, on the other hand, the view contains all the relevant data. Another difference with relational views is that with the richer nested object model, view processing and view maintenance algorithms are substantially different.

3.1 Virtual Views

We start by defining *virtual views* to be the results of queries, as illustrated by the following example.

Example 3: A view on GSDB

Suppose that we are interested in all persons named ‘John’ from the database `PERSON`. We write:

```

define view VJ as:      SELECT      ROOT.* X
                        WHERE      X.name = 'John'
                        WITHIN     PERSON

```

(3.2)

In this case, objects P1 and P3 are selected, so `value(VJ) = {P1, P3}`. The view VJ is an object `<VJ, view, set, value(VJ)>`. Notice that we used a new label `view` for the view object, although this label will generally not be seen by queries. □

In general, a virtual view is defined by a *view definition query*. A view is an object `<V, view, set, value(V)>` where `value(V)` is the set of OIDs returned by the view definition query. We say that an object `O` is in a view `V` if `O` is in `value(V)`. We also refer to the objects that are examined during query evaluation for a view as the *base objects* of the view; if those objects belong to some databases, we refer to them as *base databases*.

Virtual views can be used by queries in two ways. First, views can be used to constrain query results by using an `ANS_INT` clause. For example, the following query

```

SELECT      ROOT.professor X
ANS_INT    VJ

```

(3.3)

will return `{P1}` as its answer. Object P2 is in `ROOT.professor`, but was excluded from the query answer because it is not in `value(VJ)`.

In our example the `ANS_INT` clause was added by the query writer. We can also envision an authorization system where user queries are automatically expanded to include `ANS_INT` or `WITHIN` clauses for the union of views the user is authorized to access. This way users would only be able to access authorized data (or retrieve authorized data). Since views can be changed, it is easy to dynamically modify the privilege of a user.

A second way virtual views can be used is as “starting points” for queries. For instance, view VJ defined in Example 3 contains the set of person objects containing subobjects with value ‘John’. If we are interested in the age of those persons named ‘John’, we do not need to write the full query. Instead we can write the query `SELECT VJ.?.age`, which gives us all subobjects of objects in view VJ with label `age`. Thus, views can be used as important intermediate results that can be further processed by follow-on queries on the views. This can clearly make the follow-on queries much simpler.

Our view concept is quite simple: views only contain sets of objects, and do not “restructure” the objects in any way. Yet, by defining views on views, one can essentially add new structure that may be useful to applications. To illustrate, consider the views defined on the objects in Figure 2:

```

define view PROF as:    SELECT      ROOT.*.professor X
define view STUDENT as: SELECT      PROF.?.student X

```

(3.4)

In the original database, professor and student objects were reachable from `ROOT`, in any possible depth. Now we have created a database `PROF` that only contains professors, and one (`STUDENT`) that contains only

their students. (A student who is not a subobject of some professor would not be included in **STUDENT**.) Queries can now access this new “professor–student” hierarchy by using the views as starting points (e.g., by starting at **STUDENT** we only reach information on students with professors), or by constraining the queries with the views (e.g., by using a **ANS_INT** clause we restrict our answer to students with professors).

3.2 Materialized views

A *materialized view* is a stored copy of the objects in a view. The materialized copy of a view can be stored either physically close to the base databases, or at a remote site. Views are typically materialized to improve query performance and data availability, e.g., data that is expected to be accessed frequently is included in the materialized view. However, materialized views can also be used for access control and as query starting points, just as virtual views.

For a view **V**, each base object in **value(V)** has a *delegate* object in the corresponding materialized view. A delegate object is a real object with the same label and type of its original object. For now, we assume that a delegate has the same value as the original object; we will discuss some variations later. A delegate object will have a new OID as described in the follow paragraph.

We need to relate the delegate of an object back to its original. Keeping this relationship is crucial for view maintenance. We use the OIDs of view objects to record this relationship. For a base object *O*, the OID of *O*’s delegate object in a materialized view is obtained by concatenating the view OID with *O*. For example, in a materialized view *MV*, the delegate of base object *P1* has OID *MV.P1*. This approach is similar to semantic OIDs as used in [PAGM96, HY90, KKS92].

Since object identifiers in a materialized view have meaning, they cannot be changed arbitrarily. Some storage systems may not allow semantic OIDs (e.g., the system assigns its own OIDs). In such cases, the view management system can generate a table that maps the local OIDs used by the storage system to the semantic OIDs needed for view management.

A materialized view is again an ordinary GSDB, i.e., it is an ordinary object $\langle \mathbf{MV}, \mathbf{mview}, \mathbf{set}, \mathbf{value}(\mathbf{MV}) \rangle$, where **MV** is the OID of the view and **value(MV)** contains the OIDs of delegate objects. Our next example illustrates a materialized view.

Example 4: A materialized view

The following expression defines the materialized copy of the view in Example 3.

```

define mview MVJ as:      SELECT      ROOT.* X                (3.5)
                          WHERE        X.name = 'John'
                          WITHIN       PERSON

```

We use the keyword **mview** to specify that the view is materialized. The materialized view **MVJ** is shown in Figure 3. Each object in **obj(VJ)** has a delegate in the materialized view. The view object **MVJ** is also shown in the figure. □

Figure 3: Materialized view database

Whether a view is materialized or not should not affect query results, as long as values in delegates are the same as in the original object. For example, a query posed to **MVJ** should return the same results as when the query is posed to **VJ**. Notice that making delegates contain the same value as their original means that delegates may contain OIDs of base objects. For example, **N1** in view **MVJ** is an OID of an object in database **PERSON**. A user query on **MVJ** can access **N1** if the query allows access to remote objects (e.g., no **WITHIN MVJ** clause).

Relationships (edges) between objects in a materialized view are implicitly kept. For example, **P3** is a child object of **P1** in database **PERSON**. In **MVJ**, $value(MVJ.P1)$ contains **P3**. It is possible for the system that implements this view to detect the existence of **MVJ.P3** in the view, then change **P3** in $value(MVJ.P1)$ to **MVJ.P3**. We call this operation *swizzling the edge* from **MVJ.P1** to **MVJ.P3**. It means changing a base OID to the OID of its delegate. Swizzling should not affect the results of queries.

The system or its manager may decide to swizzle edges to improve performance. In particular, there are two scenarios where swizzling is very useful. One is when the materialized view is stored at a site different from the base databases. In this case edge swizzling may enhance query performance by allowing local access to the referenced objects. A second scenario is when a query uses a materialized view **MV** as a starting point and also contains a **WITHIN MV** clause. In this case swizzling makes it easier to enforce the **WITHIN MV** clause. For example, a query **SELECT MVJ.professor.student WITHIN MVJ** should return **MVJ.P3** in the answer object. If edge swizzling is done, it is easy to check that the edges traversed are in **MVJ** (i.e., check that pointers start with the **MVJ** identifier). Without swizzling, when the system decides to follow the link in **MVJ.P1** to **P3**, it must then check if the delegate for **P3** is in **MVJ**. Since it is (i.e., **MVJ.P3** exists), then **MVJ.P3** is added to the answer.

Since a materialized view is stored independently from the base data, it is possible to “manually” change the object values without affecting base objects. However, this has to be done with care since queries on the modified view may give different results from the original materialized view (or from the equivalent virtual view). Furthermore, changing the view in an arbitrary way makes it impossible to maintain the view automatically.

Nevertheless, there may be cases where modification of materialized views could be useful. For example, say we chose to swizzle all edges in a materialized view **MV**, and then remove all remaining base OIDs that

appear in delegate objects. As a result, any later user query using objects in **MV** will be restricted to access only **MV** objects. This “access control” is similar to attaching a **WITHIN MV** clause to all queries, but is not identical. (With the **WITHIN** clause, a query can still retrieve a view object that contains OIDs of base objects.) A second use of view modification could be to add timestamps or other auxiliary information to delegate objects. For instance, the system could add a timestamp subobject to all set objects as they are inserted into the materialized view, indicating when the object was added or modified (or even when the object was last accessed by a query). Queries can then refer to this auxiliary information, something they could not do on the equivalent virtual view.

Notice that if a remote site defines several views that share common objects, it may end up with multiple delegates for the same base object. The notion of a *view cluster* avoids this, by making all views in a cluster share delegates. Due to space limitations we do not discuss this further.

3.3 Querying views

Conceptually, a view is the same as an ordinary database, and objects in a view can be queried just like those in a GSDB. How the system processes a query on a view depends on whether the view is materialized or not. If the view is materialized, then the system accesses the stored objects and there is really no difference over normal query processing. (A materialized view must be kept up to date as the base data changes. This is the topic of the following section.)

When a view is virtual, one way to process a query over the view is to rewrite the query into an equivalent query that uses base objects only, just like query rewriting for relational views. However, since we lack an algebraic representation of queries, brute force rewriting may result in huge queries that are difficult to optimize [AGM⁺97].

Another method for answering queries on virtual views is to materialize the view when it is queried. Then the query is evaluated using the materialized view. The problem with this method is that the view could contain a large number of objects and the query could access a small number of them, thus resulting in a lot of wasted work.

In summary, we expect view definitions to be relatively simple, unlike relational views. For virtual views, simplicity makes query rewriting feasible. For materialized views, as we will see, simplicity makes maintenance feasible. More complex views and relationships may be break into multiple simple stages (multiple simple views).

4 Incremental maintenance algorithm for simple views

An incremental view maintenance algorithm produces changes to a view given the changes to base objects. Incremental view maintenance algorithms have been developed for the relational model in both centralized and distributed cases [GMS93, GL95, ZGMHW95]. In this section we develop an algorithm for GSDB views

in a centralized system, where the base databases and the materialized view reside at the same site. In this environment, the view maintenance algorithm has direct access to the base data. In the next section we will consider how to adapt the algorithm to a distributed warehousing environment. We first briefly review basic updates in a GSDB, then describe the type of view that we will develop a maintenance algorithm for. We then design the incremental view maintenance algorithm, illustrate it by examples and discuss why this new algorithm is necessary.

4.1 Basic updates of GSDB

We consider three types of basic updates on a GSDB. Let N , N_1 and N_2 be OIDs.

1. $insert(N_1, N_2)$ adds the OID of N_2 into $value(N_1)$, N_1 must have a *set* type; object N_2 becomes a child of N_1 after this operation.
2. $delete(N_1, N_2)$ removes OID N_2 from $value(N_1)$, assuming that N_2 was a child object of N_1 . (If no objects point to N_2 any more, N_2 may be garbage collected. However, we do not discuss garbage collection here.)
3. $modify(N, oldv, newv)$ changes the value of atomic object N from $oldv$ to $newv$.

The insertion and deletion operations add and delete edges in the base database graph. There are other possible update operations on a GSDB, for instance, the creation of a new object. Creating a new object that is not pointed at by any other object will have no impact on any queries, hence it has no effect on any views. Adding a new object O to a database DB can be modeled as $insert(DB, O)$. Most of other update operations on a GSDB can be represented as a series of base updates. For example, changing the value of a set object can be treated as insertions and deletions of its components. Changing the value of a label is also possible but not considered here.

4.2 Simple materialized view

We focus on a group of simple views, where the view definition query involves only tree paths instead of path expressions. We believe that studying this simple type of view illustrates the fundamental problems of view maintenance. A few examples of those problems are: When does a base update cause a materialized view to be changed? How can one determine which object(s) are to be inserted into or deleted from a view? Is incremental view maintenance more efficient than recomputing the entire view? In Section 6 we briefly discuss how to relax our assumptions and maintain more general views.

In this section, a materialized view **MV** is defined by the following expression.

```

define mview MV as:      SELECT      ROOT.sel_path X
                          WHERE      cond(X.cond_path)
                                                                    (4.6)

```

In the above expression, the selection path starts from object `ROOT`. The two paths `sel_path` and `cond_path` each contains a sequence of object labels without wild cards. Function `cond()` is as defined in Section 2; it returns `true` if any of the object values in `X.cond_path` makes the condition true.

As stated above, we assume that the base database has tree structure. The materialized view `MV` contains a set of delegate objects. From Section 3, we know that a new view object will be generated for each view defined. View object `MV` has type `set` and its components are all the delegate objects in this view.

Example 5: Basic update and corresponding view maintenance

Say we are interested in professors who are younger than 45. We define a view `YP` using the objects in Example 2.

```
define mview YP as:      SELECT      ROOT.professor X      (4.7)
                        WHERE        X.age ≤ 45
```

The current materialized view is shown on the left hand side of Figure 4. The view `YP` includes a view object `YP` and an object `YP.P1` which is the delegate of base object `P1`.

Figure 4: Change of materialized view

Assume that an update `insert(P2, A2)` occurs where `A2` is an atomic object `<A2, age, 40>`. Now `P2` becomes an object that satisfies the condition in the definition of view `YP`. Therefore, `YP.P2` should be inserted into `YP`. Figure 4 shows the correct view after processing this update. \square

Notice that in a GSDB, labels of an object can be arbitrary and can be repeated. In this example, object `P2` does not have a child object with label `age` until `A2` is inserted. In other cases, one object may have two or more subobjects with the same label. Therefore there might be more than one “derivations” of a view object. The maintenance algorithm needs to consider all those scenarios.

4.3 Incremental view maintenance algorithm

When base objects are changed, intuitively, either some new delegate objects need to be inserted into the view, or some existing delegates need to be deleted from the view. The task of an incremental view maintenance algorithm is to discover those delegates. With our model of materialized views, a view is just a collection of objects, so the maintenance algorithm need not worry about maintaining edges.

We first define a few constructs used by the algorithm. In a database with tree structure, it is clear that there is at most one path between two objects, so we use $path(N_1, N_2)$ to represent the path from N_1 to N_2 . This path starts from the label of one of N_1 's direct children and ends with the label of N_2 . If N_1 is not an ancestor of N_2 , then $path(N_1, N_2) = \emptyset$. Let p_1, p_2 be two paths: $p_1 = l_1 l_2 \dots l_m$ and $p_2 = k_1 k_2 \dots k_n$. We say $p_1 = p_2$ if $m = n$ and $l_i = k_i$ for all $1 \leq i \leq n$.

Definition: Define $ancestor(N, p)$ to be the ancestor object X of N that satisfies $path(X, N) = p$. If there does not exist such an object, then $ancestor(N, p) = \emptyset$. \square

Definition: Define $eval(N, p, cond)$ to return the set of objects in $N.p$ that make $cond(N.p)$ true. The function returns \emptyset when no such object satisfies the condition. \square

In Example 5, $eval(P1, \mathbf{age}, \mathbf{cond}) = \{\mathbf{A1}\}$ because $\mathbf{A1}$ is in $P1.\mathbf{age}$ and the value of $\mathbf{A1}$ satisfies the condition given in the view definition, i.e., $value(\mathbf{A1}) \leq 45$.

When a delegate for object X is created and added to a view V as part of view maintenance, we must copy the contents of X and make the OID of the new object $V.X$. For objects with type set, we assume that OIDs in $value(V.X)$ are not swizzled, i.e., the values in $value(V.X)$ are base OIDs.

Definition: Define $Vinsert(VN_1, VN_2)$ to be the operation that creates delegate object VN_2 and inserts it into $value(VN_1)$. We assume if an object with OID VN_2 was already a child of VN_1 , then the insertion will be ignored and VN_1 stays the same. \square

Definition: Similarly, define $Vdelete(VN_1, VN_2)$ to be the operation that removes object VN_2 from $value(VN_1)$. It is the same as the *delete* operation but it operates on view objects. If VN_2 is not a child of VN_1 , then nothing happens to VN_1 after the operation. (Again, VN_2 may be garbage collected if necessary.) \square

Algorithm 1 shows how to identify objects whose delegate is to be inserted into or deleted from \mathbf{MV} . There is more than one way to identify those objects. Since our goal is to develop algorithms that will eventually apply to a distributed warehousing architecture, the algorithm we provide here isolate the computations that need access to the base databases from those that can be done without base data. Specifically, the operations that may need to examine base data are encapsulated into functions $path(ROOT, N)$, $ancestor(N, p)$ and $eval(N, p, cond)$.

The algorithm is triggered once by each update on the base objects. In a centralized environment, view maintenance can be performed by the same transaction as the triggering update, so the algorithm uses the the base databases right after the triggering update and before any further updates.

To locate objects whose delegates are potentially affected (inserted into or deleted from the view) by a base update, Algorithm 1 examines sel_path , $cond_path$ and the updated objects. In the algorithm, Y represents an object whose delegate is potentially affected, and X is Y 's atomic descendent on which the

Algorithm 1: Incremental maintenance of GSDB view MV

▷ When $insert(N_1, N_2)$ occurs:
 If $sel_path.cond_path = path(ROOT, N_1).label(N_2).p$ where p is an arbitrary path then
 Let $S = eval(N_2, p, cond)$;
 For all $X \in S$ do $Vinsert(MV, MV.Y)$ where $Y = ancestor(X, cond_path)$.

▷ When $delete(N_1, N_2)$ occurs:
 If $sel_path.cond_path = path(ROOT, N_1).label(N_2).p$ where p is an arbitrary path then
 Let $S = eval(N_2, p, cond)$;
 For all $X \in S$, let $Y = ancestor(X, cond_path)$;
 If $p = p_1.cond_path$ where p_1 is an arbitrary path then do $Vdelete(MV, MV.Y)$;
 else if $eval(Y, cond_path, cond) = \emptyset$, then do $Vdelete(MV, MV.Y)$.

▷ When $modify(N, oldv, newv)$ occurs:
 If $path(ROOT, N) = sel_path.cond_path$ then
 Let $Y = ancestor(N, cond_path)$;
 If $cond(newv)^4$, then do $Vinsert(MV, MV.Y)$;
 else if $(cond(oldv)$ and $eval(Y, cond_path, cond) = \emptyset$), then do $Vdelete(MV, MV.Y)$.

End Algorithm 1

condition is tested. After the algorithm locates Y , it tests whether the original condition that makes $MV.Y$ appear or not appear in the view has been changed because of this recent update. If so, $MV.Y$ is inserted into or deleted from the view as appropriate. Notice that when a deletion occurs and Y is an ancestor of N_1 , we can not simply delete $MV.Y$ from the view, because other descendents of Y may also make the condition true. This is a result of our non-unique label assumption. In this case, the condition on Y is reexamined. The following figures shows the relationship between the paths and objects used by Algorithm 1. The left two figures correspond to two possible objects layout scenarios when the base update is an insertion or a deletion, the rightmost figure corresponds to the base update $modify()$.

⁴The argument of $cond()$ here is a value; the function returns $true$ if that value satisfies the condition specified.

Example 6: Incremental view maintenance

The following example illustrates the execution of Algorithm 1 on the scenario of Example 5.

Step 1: Update $insert(P2, A2)$ occurs.

Step 2: Since $path(ROOT, A2) = professor.age$, $sel_path = professor$ and $cond_path = age$, it is true that $sel_path.cond_path = path(ROOT, P2).label(A2).p$ where $p = \emptyset$.

Step 3: Let $S = eval(A2, \emptyset, cond) = \{A2\}$, object $A2$ is in S because $value(A2) = 40 < 45$. So the insertion of $A2$ will enable one of $A2$'s ancestor to be inserted into the view.

Step 4: Let $Y = ancestor(A2, age) = N2$, do $Vinsert(YP, YP.N2)$. After the insertion, object $YP.N2$ appears in the view as a child of YP .

For the same view, let there be another update $delete(ROOT, P1)$. Then Algorithm 1 does the following to maintain YP .

Step 1: The algorithm finds out that $sel_path.cond_path = professor.age = path(ROOT, ROOT).label(P1).p$, and obtains $p = age$.

Step 2: Let $S = eval(P1, age, cond) = \{A1\}$.

Step 3: Let $Y = ancestor(A1, age) = P1$. Since $p = cond_path = age$, the algorithm performs $Vdelete(YP, YP.P1)$. The resulting view is the original view with object $YP.P1$ removed. \square

To prove that Algorithm 1 is correct, we need to show that starting from an initially correct materialized view, the view will be consistent with the base data after processing each update. That is, the delegates of all view objects are in MV , and there are no extra objects in MV . The details of the correctness proof are omitted here.

4.4 Discussion

In this subsection we discuss two important questions about incremental maintenance algorithms for GSDB views: (1) Is incremental view maintenance more efficient than recomputing the entire view? (2) Is using our incremental view maintenance algorithm better than using a relational model to represent both base data and views and then applying existing relational view maintenance algorithms?

In Algorithm 1, the major cost lies in evaluating functions such as $ancestor(N, p)$ that may involve access to the base databases. However, recomputing the view also involves access to the base databases. Thus, the cost of each approach actually depends on the specifics of each scenario, such as the size of the databases, the type of view, the cost of query processing and the index structure of base databases. For example, if the base database has an “inverse index” such that from each node we can find out its parent, then evaluating

$ancestor(N, p)$ is straightforward. If there does not exist such an index, evaluating the same function may require a traversal from $ROOT$ to N .

In general, incremental maintenance will be superior to recomputing the entire view if the view contains many delegate objects (in which case recomputation will be very expensive), and updates only impact a few, easily identifiable objects. The following example illustrates such a scenario that is advantageous to incremental maintenance.

Example 7: Incremental view maintenance versus recomputation

Consider a base database with the structure of Figure 5, representing a set of “relations” and their “tuples.” (Of course, since we are using a GSDB, each “tuple” can have different “attributes,” i.e., different labels in the leaf objects.) We define a view SEL that selects a set of tuples from relation r .

```
define mview SEL as:      SELECT      REL.r.tuple X      (4.8)
                          WHERE      X.age > 30
```

Figure 5: The GSDB representation of a relational database

Now the following new tuple T is inserted into object R .

```
<T, tuple, {A, F2, ..., Fn}>
  <A, age, integer, 40>
  (..... fields F2 to Fn)
```

Following are the steps taken by Algorithm 1 to process this update:

Step 1: The algorithm finds out that $sel_path.cond_path = r.tuple.age = path(REL, R).label(T).p$ and obtains $p = age$; then it computes $S = eval(T, age, cond) = \{A\}$.

Step 2: Let $Y = ancestor(A, tuple) = T$. The algorithm performs $Vinsert(SEL, SEL.T)$. The resulting view is the original view with a new tuple object $SEL.T$.

The incremental algorithm needs to evaluate $path(REL, R)$, $ancestor(A, tuple)$ and $eval(T, age, cond)$. Since the base tree is very shallow, computing these functions should not be expensive. Furthermore, if the contents

of tuple \mathbf{T} (its label, value and subobjects) can be used by the incremental view maintenance algorithm, then $ancestor(\mathbf{A}, \mathbf{tuple})$ and $eval(\mathbf{T}, \mathbf{age}, \mathbf{cond})$ are immediately available, without accessing base data.

If we go a step further and assume that the view maintenance algorithm has cached the fact that $path(\mathbf{REL}, \mathbf{R}) = r$, then view \mathbf{SEL} can be maintained without any access to base data. Of course, for another update like inserting an edge between object \mathbf{REL} and another object with label \mathbf{r} , the algorithm may still need to examine the base database. In Section 5.2 we study further how to cache auxiliary information to improve performance.

If we consider a different update, one where a tuple $\mathbf{T2}$ is inserted into relation s , we again see that incremental maintenance is simple. That is, the incremental maintenance algorithm will stop processing after it finds out that $path(\mathbf{REL}, \mathbf{S})$ does not match with the first label in $\mathbf{sel_path}$.

It is easy to see that a full view recomputation scheme could be much more expensive for this example. In particular, if the materialized view is large, many objects would have to be recreated in the materialized view each time a base update occurs. In summary, incremental maintenance will probably be superior if the selection and condition paths are relatively short, and if some of our evaluation functions such as $path()$ do not require access to base data. If, on the other hand, paths are long, then handling of an update could easily require access to very large portions of the base databases. \square

Now we look at our second discussion issue: Is it possible to represent objects of a GSDB in a relational fashion by “flattening” the object tree, as shown in the following example? Then it may be possible to use existing relational view maintenance techniques to maintain the view.

Example 8: Relational representation of graph structured data

We can represent a GSDB using three tables. The first table contains the OIDs and labels of all objects, the second table contains the OIDs of all objects of type set and their children OIDs, and the third one contains the OIDs of all atomic objects and their values. For simplicity, we assume that the VALUE attribute of the third relation can hold different data types (it is a union type).

The three-table representation of database **PERSON** in Example 2 is the following.

<u>OID</u>	<u>LABEL</u>	<u>PARENT</u>	<u>CHILD</u>	<u>OID</u>	<u>TYPE</u>	<u>VALUE</u>
ROOT	person	ROOT	P1	N1	string	‘John’
P1	professor	ROOT	P2	A1	integer	45
P2	professor	ROOT	P4	S1	salary	100k
P3	student	P1	N1	N2	name	‘Sally’
...

Using this relational representation, one could in principle incrementally maintain the view, but there are disadvantages. First of all, with the relational representation, a single object update can involve multiple tables. For example, an insertion of an atomic object needs to modify all three tables. This would require several invocations of the relational incremental maintenance algorithm, and could lead to inconsistencies

while only some of the updates are reflected on the materialized view. For example, it would be incorrect to have a tuple (A, B) in the PARENT-CHILD table without having both A and B in the OID-LABEL table.

Furthermore, a view defined using paths as in Section 3 needs to be defined by a Select-Project-Join expression with (many) self-joins. Incrementally maintaining such a view is not trivial, and we believe it could be more expensive to evaluate because the “path semantics” are hidden in the relations. Similarly, caching paths as suggested earlier will be harder to implement, again because the notion of a path is not explicit in the representation. \square

5 View maintenance in a data warehouse

In this section we consider view maintenance in a data warehousing architecture. Figure 6 shows the basic architecture of a data warehouse.

Figure 6: Data warehousing architecture

In the system, base objects are stored at the data sources, and materialized views are defined and stored at the warehouse. For each source, a *wrapper* is used to translate source data into the GSDB model if the underlying source database has another data format. The wrapper also translates queries from the warehouse (if any) to the native queries of the data source and sends the results back to the warehouse. Each source is also associated with a *source monitor* that detects the update events as described in Section 4.1 and reports them to the warehouse. The warehouse cannot control actions on source objects, but it can send queries to the source and obtain answers evaluated at the current source state.

We assume that source objects have universally unique OIDs. This can be achieved by attaching the OIDs at the source with a unique source ID. Then, delegate objects in the materialized views can use the same semantic OID method as described in Section 3 to relate back to their original objects. In reality, when a source underlying database is not object model, a source wrapper may need to use other names or key values to identify its objects.

5.1 Incremental view maintenance in a data warehouse

In the previous section we developed a centralized incremental view maintenance algorithm. When a materialized view is stored at a data warehouse that is separated from the data sources, the warehouse can apply the same algorithm. However, when only the warehouse (and not the data sources) knows the view definition, evaluating functions such as $ancestors(N, p)$ or $eval(N, p, cond)$ needs to be done by communicating with source databases.

The most straightforward way for the warehouse to implement those functions is to send queries back to the data sources. The warehouse (or the source wrappers) needs to translate the functions into one or more source queries and integrate the answers. If the source can evaluate any queries required to evaluate those functions, then the warehouse can directly apply Algorithm 1 in Section 4. When a source can only support some simple querying interface, then the warehouse can decompose the evaluation of a function into multiple simple queries, integrate the answer and evaluate the target functions.

Example 9: Realizing a function using source queries

Assume that a source accepts queries with format **fetch** X **where** $func(X)$, and returns all objects X (their OIDs and values) from this source that satisfy conditions specified in $func(X)$. Also, assume the warehouse knows that the source can evaluate function $path(X, Y)$. Then, the warehouse may translate the evaluation of $ancestor(Y, p)$ into **fetch** X **where** $path(X, Y) = p$. For $eval(N, p, cond)$, the warehouse may use **fetch** X **where** $path(N, X) = p$ to obtain all objects in $N.p$, then test condition $cond()$ on those objects locally. \square

There are two major problems with querying the sources. First, it is expensive. If the capability of a source is very limited, evaluating one function may involve many complex interactions, involving query and answer translation. Furthermore, sending queries and answers consumes time and network bandwidth, and leads to poor availability if a source is down.

Second, querying the source, especially multiple times to evaluate the same query, may result in inconsistent data. When the source is autonomous, which is often true in a warehousing environment, source updates may interfere with query evaluation and resulting in inconsistent query results [ZGMHW95]. However, the problem may be ameliorated (as compared to a relational scenario) because unique OID can be helpful in eliminating duplicates.

There are several ways in which we can reduce the number or complexity of source queries. We next describe three potential techniques, which depend on the way sources report their updates. We refer the one or two objects that are directly involved in an update U as *directly affected source objects*. For example, when $insert(N_1, N_2)$ occurs, the directly affected objects are N_1 and N_2 .

1. The source only reports the type of U and the OIDs of all directly affected source object. In this scenario, the warehouse cannot do much other than sending queries back to the sources. Some form of

object identifiers need to be sent with the queries to identify the source objects involved.

2. In addition to OIDs, the source also reports the label and value of all directly affected objects. That is, if $insert(N_1, N_2)$ occurs, the source will report the label, type and value of both N_1 and N_2 . In this scenario, the warehouse can do some local screening to avoid some querying back to the source. For example, when $label(N_2)$ is not in the $sel_path.cond_path$, $insert(N_1, N_2)$ will have no effect on the view. In Example 5, if the label of **A2** is not **age**, then the warehouse knows that the view will stay the same after the insertion of **A2**.
3. For each directly affected object N , the source will report $path(ROOT, N)$ as well as the OIDs of objects along this path to the warehouse. This is a plausible scenario because when the source does the update, it needs to traverse the source database until reaching the updated object. So the source may record the path to the updated object and report it as part of the update information. In this scenario, besides $path(ROOT, N)$, the warehouse may also obtain $Y = ancestor(X, cond_path)$ when Y is an ancestor object of N . Then, the warehouse can always maintain the view locally corresponding to base update $modify()$. However, evaluating $eval(Y, cond_path, cond)$ may still needs the values of objects in $Y.cond_path$, which can only be obtained from querying the source.

5.2 Caching

So far we have assumed that the warehouse caches nothing but the materialized views. All other information at the warehouse are either obtained from the reported source updates, or from querying back to the source. However, the warehouse may be able to store auxiliary data structures to avoid, or at least reduce the need to query the source. The following example illustrates this point.

Example 10: Caching auxiliary information to improve view maintenance

Let us consider the same view in Example 5.

```
define mview YP as:      SELECT      ROOT.professor X      (5.9)
                        WHERE        X.age ≤ 45
```

Assume that the warehouse caches the following information for this view:

In this case, view maintenance corresponding to any base update can be done locally at the warehouse given the directly affected objects and, if the update is an insertion of a professor **P** into **ROOT**, the direct

subobjects of P . The functions used by the algorithm, like $path(ROOT, A)$ can always be obtained from the auxiliary structure and the update information.

In general, for a view whose select path starts from object OBJ , say the warehouse caches all objects and labels reachable from OBJ along $sel_path.cond_path$. Then the warehouse can maintain the view locally, for any base update. Of course, caching all these information is sufficient but not necessary. For instance, the warehouse may choose to cache part of the above structure, e.g., without the values of atomic nodes (which may be large because they may contain images). With partial caching, some simple queries may need to be sent back to the source to test a condition.

Notice that the auxiliary structure itself needs to be maintained. That is, the auxiliary data is simply another materialized view, and can be maintained using our algorithm (if it can be expressed as a simple view). However, the auxiliary data structure may be compressed, or may be shared by more than one views. The implicit assumption is that the overhead of maintaining the auxiliary data is small, for example, it could be always maintainable locally at the warehouse. \square

Maintenance can also be improved with knowledge of paths that can *never* occur or *always* occur at the source. For example, assume that the warehouse knows that at the source objects labeled **student** do not have a child object with label **salary**. Consider then a view **ST** defined by `SELECT ROOT.student.?`, which select all direct children of student objects. Then when a source update $modify(X, ov, nv)$ occurs and $label(X) = \mathbf{salary}$, the warehouse knows that view **ST** is unaffected. This path knowledge can be considered a type of “schema” for certain objects and their children [GW97].

6 Conclusion

In this paper we studied the definition and realization of GSDB views. We provided a procedural algorithm for maintaining one type of view and discussed how to realize it in a data warehouse environment. We believe that our method for view definition, materialized view storage and management serve as a first step in solving the practical problem of GSDB views.

We only developed an incremental view maintenance algorithm for a group of simplified views to illustrate the fundamental problems. Due to space limitation, we cannot describe in detail how more general materialized views can be maintained. However, note that relaxing some of the restrictions we imposed on the view definition in Section 4 is easy. For example, handling views with more than one select path or more than one condition is straightforward. On the other hand, relaxing the following two assumptions (which we believe is important to do for some applications) is not simple:

- Allow the `sel_path` and `cond_path` to be general path expressions with wild cards. To maintain this type of view, the maintenance algorithm needs to be able to test path containment for general path expressions. For example, any path p is contained in path expression $*$. If a view is defined by

expression `SELECT ROOT.*`, then any insertion of a `ROOT`'s descendent node will cause delegate objects to be inserted into the view.

- Allow more complex structure of base databases, for example, allow base databases to be directed acyclic graphs (DAGs). The maintenance algorithm will be similar to Algorithm 1, except that now there may be more than one path between two objects. Therefore, the actual implementation of the algorithm, e.g., computing $ancestor(X, p)$, is more difficult.

In addition to the maintenance algorithms for more general views, there are other open challenging issues for GSDB views that we are starting to address. In closing, we illustrate some of these issues.

- How does one define and maintain views whose edges (relationships) can be explicitly shown or hidden?
- How does one define and handle views in which the value of one delegate object is obtained from more than one base objects, for example, aggregate views?
- How does one define and maintain partially materialized views, for example, views that materialize a few levels of objects and leave the rest as pointers back to base data? This type of views may be useful for caching some but not all data of interest.
- How does one maintain materialized views when not only the updated base objects, but also the update query that generated them is known? For example, we may know what the salary of each person named 'Mark' was increased by \$1000. Then a view containing the salary of persons named 'John' should be unaffected.
- How does one maintain a cluster of interrelated materialized views efficiently?

Acknowledgments

We would like to thank Janet L. Wiener, Serge Abiteboul and other members of the Stanford database group for discussions related to some of the ideas in this paper.
