Stanford University

Abstract. We consider the problem of estimating the length of a shortest path in a DAG whose edge lengths are known only approximately but can be determined exactly at a cost. Initially, each edge e is known only to lie within an interval $[l_e, h_e]$; the estimation algorithm can pay c_e to find the exact length of e. In particular, we study the problem of finding the cheapest set of edges such that, if exactly these edges are queried, the length of the shortest path will be known, within an additive $\kappa > 0$ that is given as an input parameter. We study both the general problem and several special cases, and obtain both easiness and hardness approximation results.

1 Introduction

Consider a weighted DAG G with a single source s of in-degree zero and a single sink t of out-degree zero, whose exact edge lengths are not known with certainty. Assume that for every edge e of G the length of e is only known to lie in an interval $[l_e, h_e]$. The length of a path in G can be computed with uncertainty and represented as an interval containing the exact length. An interval containing the length of the shortest path between two nodes in G can similarly be computed.

Suppose that for every edge e, the exact length of e can be found at query cost c_e. An optimization problem that arises naturally is: *Given a DAG G, a source s, a sink t, a set P of s-t paths, edge-length intervals $[l_{e_1}, h_{e_1}], \ldots, [l_{e_m}, h_{e_m}]$, edge query costs $c_{e_1} \ldots c_{e_m}$, and precision parameter κ, find a minimum-cost set of edges $E' = \{e_{i_1}, \ldots, e_{i_k}\}$ such that if exactly the edges in E' are queried, an interval of width at most κ can be identified, that is guaranteed to contain the length of the shortest $p \in P$.* P may be given explicitly, it may be specified

implicitly, or it may not be specified at all, in which case P can be assumed to be the set of all s-t paths in G. It turns out that an actual s-t path, of length within κ of the shortest s-t path, will be obtained as well. Note that there are two natural versions of this problem. In the *online* version, the sequence of queries is chosen adaptively — each query is answered before the next one is chosen. In the *offline* version, the entire set of queries must be specified completely before the answers are provided, and it must be *guaranteed* that the length of the shortest path can be pinned down as desired, regardless of the results of the queries. In this paper we consider the offline formulation of the problem.

The problem of finding a cheap set of edge queries is neither in NP nor co-NP unless NP = co-NP; however, it is in the class Σ_2. We therefore study the hardness of the problem under various types of restrictions. The special case of zero-error is solvable in polynomial time if the set of paths is given explicitly or has a particular type of implicit description. If P is given explicitly, then the number of paths we consider is clearly polynomial in the size of the input, and the zero-error problem has a polynomial-time solution; we also show that if P admits a recursive description as defined later, which includes the case of series-parallel graphs, it can be analyzed in polynomial time. If the set of paths is unrestricted, however, for all $\delta > 0$ the zero-error problem is hard to approximate within $n^{1-\delta}$, even if the error *and* cost requirements are relaxed substantially. In order to obtain polynomial algorithms or reasonable approximation bounds, we must therefore consider suitable restrictions on the structure of instances of the problem. In many cases, under such restrictions we obtain matching upper and lower bounds.

We consider the case in which κ may be greater than zero, and examine different types of restrictions on the path structure of the graph. The first such restriction is the unique-upper-length requirement — that all paths in the graph have the same upper bound on length. This restriction alone is not enough to make the problem tractable. With certain assumptions on κ, the length intervals, and the edge structure, however, the problem can be solved in polynomial time or with small approximation factors. We consider restrictions on κ, restrictions on the edge structure of the graph, and restrictions on the number and types of nontrivial edges (i.e., edges whose lengths are not known exactly) on the paths under consideration.

1.1 Motivation and Related Work

Our problem is motivated by the work of Olston and Widom [11] on query processing over replicated databases, where local cached copies of databases are used to support quick processing of queries at client sites. There is a master copy of the data where all the updates to the database are maintained. The frequency of updates makes it infeasible to maintain exact consistency between the cached copies and the master copy, and the data values in the cache are likely to become stale and drift from the master values. However, the cached copies store for each data value an interval that is guaranteed to contain the master value. Systems

considerations sometimes make it desirable to perform all queries to the master copy en masse; in this case, the offline formulation is much more relevant.

In some cases, the data appears as a graph with edges whose lengths are updated over time, and queries request a short path between two nodes. It is desirable to find a path whose length is within κ of that of the shortest, where the value of κ is specified along with the query. This problem has applications in areas such as network monitoring and computerized route selection for cars. Here, edge lengths may change rapidly, and excessive queries will result in high communication costs.

Another class of queries, aggregation with uncertainty, has been studied in the context of the interval caching framework. Olston and Widom [11] consider aggregation functions such as *sum*, *min*, and *max* for the offline formulation. The shortest-path problem we consider in this paper is a strict and common generalization of all three of these aggregation functions. Feder *et al.* [4] consider both the online and the offline formulations of the selection problem, with *median* as a special case. Finally, Khanna and Tan [8] extend some of the results for the selection and sum problems, focusing on other precision parameter formulations. In the model of Papadimitriou *et al.* [12, 3] (similar to the above-described online model), a robot tries to learn the map of a Euclidean region, keeping its travel distance competitive with the cheapest proof to the map. Karasan *et al.* [7] and Montemanni and Gambardella [10] assume a digraph with source and sink and, for each edge, an interval containing the length; they study how to find a path with lowest worst-case length (resp. worst-case competitive ratio) [1].

2 The Zero-Error Case

We consider first the case with no error, i.e., $\kappa = 0$. Consider two paths p and q from s to t in P. Let L be the sum of l_e over edges e in p but not in q. Let H be the sum of h_e over edges e in q but not in p. Say that p *dominates* q if $L > H$, or if $L = H$ and p and q do not have the same nontrivial edges (edges e with $l_e \neq h_e$).

Proposition 1 *A choice of edges e to query guarantees zero error if and only if it queries all the nontrivial edges in each path $p \in P$ that does not dominate any path $q \in P$. (The zero-error problem is thus in co-NP.)*

Proof Sketch: Suppose a nontrivial edge e is in a path p that does not dominate any path q. Then for every path q that does not have the same nontrivial edges as p we have $L \leq H + \delta$ for some $\delta > 0$; we can choose δ smaller than the length of the interval for e. Therefore, if we query all edges f other than e, and obtain the answer l_f for f in p, and the answer h_f for f not in p, then the resulting interval will contain at least $[L_0, L_0 + \delta]$, where L_0 is the resulting length of the path p when we choose l_e for e as well.

[1] Here, the competitive ratio of an s-t path, given some assignment of lengths to edges, is its total length, divided by that of the shortest path.

If p dominates some q, then we can ignore p because for all possible answers to the queries, the length of p is at least the length of q, and the domination relation is acyclic. □

Theorem 1 *If the collection P is given explicitly, then the zero-error problem can be solved in polynomial time.*

For the proof, observe that by Proposition 1, it suffices to test for each path p in P whether p dominates some q in P, and query all edges in p if it does not.

We consider next the following *implicit description* of P for G. Either (1) G consists of a single edge $e = (s, t)$, and P has the single path given by e; or, (2) We are given an implicit description of P' for G' with source s and sink t, where G' contains an edge $e = (s', t')$, and we are also given an explicit description of P'' for G'' with source s' and sink t'. The graph G is obtained by taking G' and replacing e with G''; the paths P are obtained by taking the paths P' and replacing the occurrences of e in these paths with each of the paths in P''.

Proposition 2 *In the implicit description of P for G, suppose that each explicit description of P'' for G'' used contains all the paths in G''. Then P contains all the paths in G. In particular, if G is a series-parallel graph, then each such G'' consists of just two edges (either in series or in parallel), giving a polynomial description for all paths in G.*

For the proof, note that all paths in G correspond to paths in G' which may go through the special edge e, and if they do, to a choice of path in G''. The result follows by induction. A series-parallel graph can be reduced to a single edge by repeatedly replacing G'' consisting of two edges in series or two edges in parallel with a single edge.

Theorem 2 *If the collection of paths P for G is implicitly presented as described earlier, then the zero-error problem can be solved in polynomial time.*

Proof Sketch: Suppose p in P dominates some q in P. We may choose q so that p and q have the same edges from s to some s', are disjoint from s' to some t', and have the same edges from t' to t.

Simplify the graph G by repeatedly replacing the components G'' with single edges, until we obtain a component G'' containing both s' and t', for all choices of s' and t'. In this component G'', consider all pairs of paths p'' and q'' from P''; some such pair corresponds to p and q.

We can then determine the values L and H for p'' and q''. To determine H, choose h_f for all edges f in q'' not in p''. If such an edge f corresponds to a subcomponent, find the shortest path in that subcomponent corresponding to taking h_g for each edge g in the subcomponent. To determine L, choose l_f for all edges f in p'' not in q''. If such an edge f corresponds to a subcomponent, find the shortest path in that subcomponent corresponding to taking l_g for each edge g in the subcomponent; here, however, we only consider paths in the subcomponent that do not dominate other paths, which we can assume have been precomputed

by the same algorithm. We also only consider paths going through the edge e being tested for membership in a path p that does not dominate any q. □

Theorem 3 *If P consists of all the paths in the given G, and each $[l_e, h_e]$ is either $[0,0]$ or $[0,1]$, the zero-error problem is co-NP-complete; in the unit-cost case it is hard to approximate within $n^{1-\delta}$, for any constant $\delta > 0$. In fact, it is hard to distinguish the case where there is a zero-error solution of cost w from the case where there is no solution of error at most $\kappa = n^{\delta_1}$ and cost at most wn^{δ_2} for all constants $\delta_1, \delta_2 > 0$ satisfying $\delta_1 + \delta_2 < 1$.*

Proof Sketch: We show that testing whether an edge e belongs to some path p that does not dominate any path q is NP-complete. The reduction is from 3-colorability.

We will construct a DAG as follows. We have a DAG S with source s and sink s', where all edges have interval $[0,1]$, and a DAG T with source t' and sink t, where all edges have interval $[0,1]$. The edge e goes from s' to t'. There is also a set E of edges with interval $[0,0]$ from vertices in S to vertices in T. The required path p consists then of a path p_S in S from s to s' and a path p_T in T from t' to t. Such a path does not dominate any other path if and only if no edge in E joins a vertex in p_S and a vertex in p_T.

Let G be the instance of 3-colorability, with vertices $v_1, \ldots, v_n$ and edges $e_1, \ldots, e_m$. The DAG S, in addition to s and s', has vertices $(v_i, 1)$, $(v_i, 2)$ and $(v_i, 3)$ for each v_i in G. The edges in S go from each (v_i, j) to each (v_{i+1}, j'), plus edges from s to each (v_1, j) and from (v_n, j) to s'. The path p_S thus chooses a (v_i, j) for each v_i, i.e., assigns color j to v_i.

The DAG T, in addition to t' and t, has vertices $(e_l, 1, 1)$, $(e_l, 2, 1)$, $(e_l, 3, 1)$, $(e_l, 1, 2)$, $(e_l, 2, 2)$, $(e_l, 3, 2)$ for each e_l in G. The DAG T has a path from t' to t going through all $(e_l, j, 1)$; the $(e_l, j, 2)$ are connected similarly to the $(e_l, j, 1)$. Thus the path p_T chooses a k in (e_l, j, k) for each e_l, j.

If G has an edge $e_l = (v_i, v_{i'})$, Then E has the edges $((v_i, j), (e_l, j, 1))$ and $((v_{i'}, j), (e_l, j, 2)$. Thus p_T will be able to choose a k in (e_l, j, k) for e_l, j if and only if v_i and $v_{i'}$ are not both assigned color j. Thus the choice of paths p_S, p_T corresponds to a 3-coloring of G.

This gives NP-completeness. The hardness of approximation follows from the fact that the special edge e can be given an arbitrarily large cost, much larger than the sum of all the other costs. In the unit cost case, we can use a large number of parallel edges for e to achieve the same effect as a large cost, and insert extra edges of length $[0,0]$ if parallel edges are not allowed. Thus, with unit costs, we have m_0 edges other than e, and $m_0^c \approx n$ edges corresponding to e, giving an approximation hardness of $m_0^{c-1} = n^{1-\delta}$.

The stronger hardness of approximation follows by replacing each edge with length $[0,1]$ with a path of r edges of length $[0,1]$. Then we have $m_0 r$ edges other than e, and $m_0^c r \approx n$ edges corresponding to e. Setting $r = n^{\delta_1}$, $m_0^{c-1} = n^{\delta_2}$, and $m_0 = n^{1-\delta_1-\delta_2}$ gives the result. □

3 The Unique-Upper-Length Case

We now allow error $\kappa \geq 0$. For each edge e with interval $[l_e, h_e]$ we assume both l_e and h_e are integer. This implies that only integer κ is interesting. The unique-upper-length case is the case where there is an integer H such that for each path p from s to t, $\sum_{e \in p} h_e = H$.

Proposition 3 *In the unique-upper-length case, a choice of queried edges guarantees error κ if and only if it guarantees error κ for each path from s to t in P. (The unique-upper-length problem is thus in NP.)*

We assume next that P consists of all paths from s to t. Let $K \leq H$ denote the total error when no interval is queried.

Theorem 4 *The unique-upper-length case can be solved in polynomial time for $\kappa = 0, 1, K-1, K$.*

Proof Sketch: Error $\kappa = K$ requires no queries, while $\kappa = 0$ requires querying all nontrivial intervals (by Proposition 3).

Suppose $\kappa = K - 1$. We must query at least one edge in each path p such that the sum of the lengths of the intervals $[l_e, h_e]$ over edges e in p equals K. Choose the l_e values for all edges e, and compute for each vertex v the length l_v of the shortest path from s to v. Then $K = H - l_t$. The sum of the lengths of the intervals $[l_e, h_e]$ over edges $e = (v, v')$ in p equals K if and only if $l_v + l_e = l_{v'}$ for all such e. Therefore, if we remove all edges e with $l_v + l_e > l_{v'}$, then we must query at least one edge for each path p from s to t in the resulting graph. This is the same as computing a minimum cost cut between s and t, which can be obtained by a maximum flow computation.

Suppose next $\kappa = 1$. Then all edges e with interval $[l_e, h_e]$ such that $h_e - l_e > 1$ must be queried, and all but at most one of the edges e with interval $[l_e, h_e]$ with $h_e - l_e = 1$ on a path p must be queried. Define an associated graph G' whose vertices are the edges e with $h_e - l_e = 1$, with an edge from e to e' in G' if e precedes e' in some path p. The graph G' is transitively closed, and paths p correspond to cliques in G'; we must therefore query all but at most one e in each such clique, i.e., the queried edges must form a vertex cover in G'.

Suppose e has incoming edges from A and outgoing edges to B in G'. Since G' is transitively closed, it also has all edges from A to B, and thus a vertex cover must choose all of A or all of B. Replace e with two vertices e_1, e_2, so that e_1 has the incoming edges from A and e_2 has the outgoing edges to B. Then a vertex cover will only choose at most one of e_1, e_2, since it chooses all of A or all of B. Furthermore, a vertex cover choosing e corresponds to a vertex cover choosing one of e_1, e_2, and vice versa. If we apply this transformation for each e, then each vertex e_1 has only incoming edges and each vertex e_2 has only outgoing edges. Therefore the graph is a bipartite graph, with vertices e_1 in one side and vertices e_2 in the other side. A minimum cost vertex cover in a bipartite graph can be obtained by a maximum flow computation. □

Theorem 5 *The unique-upper-length case is NP-complete, and hard to approximate within* $1+\delta$ *for some* $\delta > 0$*, if* $2 \leq \kappa \leq K-2 \leq H-2$*. This includes the case* $K = H = 4$ *and* $\kappa = 2$*, even if: (1) all* $[l_e, h_e]$ *intervals are* $[0,0], [0,1]$*, or* $[0,2]$*, with at most four nontrivial intervals per path (which has a 2-approximation algorithm); or, (2) all* $[l_e, h_e]$ *intervals are* $[0,1], [0,2]$ *or* $[1,1]$*, with at most three nontrivial intervals per path (which has a 1.5-approximation algorithm).*

Proof Sketch: Suppose $K = H = 4$ and $\kappa = 2$. We do a reduction from vertex cover for a graph G. In fact, we consider vertex cover for a graph G' obtained from G by replacing each edge (v, v') in G with a path (v, x, y, v') of length 3 in G'. The optimal vertex covers are related by $\text{opt}(G') = \text{opt}(G) + |E(G)|$.

The DAG has a vertex v for each v in G, and a corresponding edge (s, v) with interval $[0,1]$. For each edge (v, v') in G, the DAG has two extra vertices a, b, an edge (v, a) with interval $[0,2]$ corresponding to x, an edge (a, t) with interval $[0,1]$ corresponding to y, an edge (v', b) with interval $[0,1]$ of very large cost that will not be queried, and an edge (b, a) with interval $[0,1]$ of zero cost that will be queried for Case (1) or with interval $[1,1]$ for Case (2).

For the paths (s, v, a, t), we must either query (v, a) corresponding to x or query both (s, v) and (a, t) corresponding to v and y respectively. This corresponds to covering the two edges (v, x) and (x, y). For the paths (s, v', b, a, t) we must query either (s, v') or (a, t) corresponding to v' and y respectively. This corresponds to covering the edge (y, v'), completing the reduction.

If only unit costs are allowed, then for Case (2) use a large number of parallel paths (v', b, a) from v' to a to simulate a large cost. For Case (1), use parallel edges to simulate cost, and add edges with interval $[0,0]$ if parallel edges are not allowed.

This proves NP-completeness. For the hardness of approximation, take G of maximum degree d for some constant $d \geq 3$, for which vertex cover is known to be hard to approximate within $1 + \delta$ for some $\delta > 0$ [2]. We know that the optima r, r' for G, G' are related by $r' = r + m$, where $m = |E(G)|$. Furthermore $r \geq \frac{m}{d}$. Therefore $r = \frac{r}{d+1} + \frac{rd}{d+1} \geq \frac{r}{d+1} + \frac{m}{d+1} = \frac{r'}{d+1}$, so an excess of δr for the vertex cover obtained in G corresponds to an excess of $\frac{\delta}{d+1} r'$ for the vertex cover obtained in G', giving hardness within $1 + \frac{\delta}{d+1}$ for G' and hence for the corresponding DAG with source s and sink t.

To obtain the result for any κ, K, H with $2 \leq \kappa \leq K - 2 \leq H - 2$, insert right after s a path with $H - K$ edges with interval $[1,1]$, and $K - 4$ edges with interval $[0,1]$ of which $\kappa - 2$ have very large cost and will not be queried, and $K - \kappa - 2$ have zero cost and will be queried. Again large different costs can be simulated with different numbers of parallel paths of two edges in the unit cost case.

The approximation upper bounds follow from Corollary 1 in Section 4. □

Theorem 6 *The unique-upper-length case has a* $(K - \kappa)$*-approximation algorithm; and for all integers* d *has an* $(\frac{\kappa}{d} + d)$*-approximation algorithm, in particular a* $(2\sqrt{\kappa} + 1)$*-approximation algorithm. We can get a 2-approximation with respect to the optimum cost for a given* κ *if we allow replacing the error* κ *by* 2κ *as well.*

In the case where all intervals $[l_e, h_e]$ satisfy $h_e - l_e \leq 1$, we get an $H_{K-\kappa} \leq 1 + \log(K - \kappa)$ approximation algorithm, where $H_v = \sum_{1 \leq i \leq v} \frac{1}{v} \leq 1 + \log v$; and for all integer d an $(\frac{\kappa}{d} + 1 + H_{d-1})$-approximation algorithm, in particular a $(3 + \log \kappa)$-approximation algorithm.

Proof Sketch: We give the $(K - \kappa)$-approximation algorithm. Let $\mu = K - \kappa$, and let w be the cost of the optimal solution r_0. Suppose we have found a solution r that reduces the error by $\lambda \leq \mu - 1$. We shall find extra edges of total cost at most w which when combined with the solution r reduce the error by at least $\lambda + 1$. Applying this at most μ time yields the result.

For each edge e in r, replace its interval $[l_e, h_e]$ with $[h_e, h_e]$. The extra edges must reduce the error in this new graph by at least 1, and an optimal solution for this problem can be obtained from Theorem 4. This optimal solution has cost at most w because the edges in r_0 and not in r provide such a solution and have cost at most w.

We give the $(\frac{\kappa}{d} + d)$-approximation algorithm. We consider the linear programming relaxation of the problem. We introduce a variable $0 \leq x_e \leq h_e - l_e$ for each edge e. The idea is that $x_e = 0$ if e is queried and $x_e = h_e - l_e$ if e is not queried. We want the longest path using the x_e values to be at most κ. This can be expressed by introducing a variable y_v for each vertex, and adding the conditions $y_s = 0$, $y_t \leq \kappa$, and $y_{v'} \geq y_v + x_e$ for each edge $e = (v, v')$. The objective function to be minimized is $\sum_e w_e(1 - \frac{x_e}{h_e - l_e})$. Let w be the value of the optimum. If we query all edges for which $1 - \frac{x_e}{h_e - l_e} \geq \frac{d}{\kappa + d}$, we incur cost at most $\frac{\kappa + d}{d} w$. For each path p from s to t we have $\sum_{e \in p} x_e \leq \kappa$. For each edge e in p not queried, we have $1 - \frac{x_e}{h_e - l_e} < \frac{d}{\kappa + d}$, or $h_e - l_e < \frac{\kappa + d}{\kappa} x_e$. Therefore the sum of the lengths $h_e - l_e$ of intervals over edges e in p not queried is at most $\kappa + d - 1$. So we must reduce the error further by $d - 1$. After replacing the intervals for edges e previously queried with $[h_e, h_e]$, this will cost at most $(d - 1)w$ by the previous result. The total cost is thus at most $(\frac{\kappa + d}{d} + d - 1)w = (\frac{\kappa}{d} + d)w$, as required.

The remark on doubling both the cost of the optimum and the error allowed follows from setting $d = \kappa$ in the linear programming rounding.

Suppose now all intervals $[l_e, r_e]$ satisfy $r_e - l_e \leq 1$. We give the $H_{K-\kappa}$-approximation algorithm. Let $\mu = K - \kappa$, and let w be the cost of the optimal solution r_0. Suppose we have found a solution r that reduces the error by $\lambda \leq \mu - 1$. We shall find extra edges of total cost at most $\frac{w}{\nu}$ for $\nu = \mu - \lambda$ which when combined with the solution r reduce the error by at least $\lambda + 1$. Applying this at most μ times yields the result.

For each edge e in r, replace its interval $[l_e, h_e]$ with $[h_e, h_e]$. The extra edges must reduce the error in this new graph by at least 1, and an optimal solution for this problem can be obtained from Theorem 4. We must show that this optimal solution costs at most $\frac{w}{\nu}$. The edges in r_0 and not in r reduce the error in this graph by at least ν: call these edges r_1. Assign to each edge e the value l_e, and compute for each vertex v the length l_v of a shortest path from s to v. A solution must query at least one nontrivial edge in each path p such that every nontrivial

edge $e = (v, v')$ in p has $l_{v'} - l_v = l_e$, that is, in every path p after we remove all edges e that have $l_{v'} - l_v < l_e$. Now every path p has at least ν edges in r_1, so we can divide the edges in r_1 into ν sets such that each set is a cut: the ith set contains all the edges that occur at the earliest as the ith edge from r_1 in some path p. Thus, some such set constitutes a cut with cost at most $\frac{w}{\nu}$. The optimal solution from Theorem 4 then has cost at most $\frac{w}{\nu}$ as well.

The $(\frac{\kappa}{d} + 1 + H_{d-1})$-approximation algorithm follows as before. We incur cost $\frac{\kappa+d}{d}w$ to reduce the error to at most $\kappa + d - 1$ by linear programming, and we then incur cost $H_{d-1}w$ to reduce the error to κ by the algorithm just described. □

Theorem 7 *The unique-upper-length case on series-parallel graphs has a $(1+\delta)$-approximation algorithm for all $\delta > 0$, and an exact polynomial time algorithm if κ is bounded by a polynomial.*

Proof Sketch: We compute an optimal solution on G for all $\kappa' \leq \kappa$. If G consists of two graphs G_1, G_2 in parallel, then we must have a solution for κ' on each of G_1, G_2. If G consists of two graphs G_1, G_2 in series, then we must have a solution for κ_1 on G_1 and a solution for κ_2 on G_2 with $\kappa_1 + \kappa_2 = \kappa'$. We can try all such decompositions of κ'. The result follows by induction on the structure of G, when κ is bounded by a polynomial.

For larger κ, we introduce an approximation factor of $1 + \frac{\delta}{n}$, and do a binary search for possible values of κ', stopping each branch of the binary search when the solutions for two consecutive values of κ' differ by a factor of at most $1 + \frac{\delta}{n}$. Thus, a polynomial number of solutions will be maintained. When the solutions for G_1, G_2 are combined to obtain solutions for G, the number of solutions obtained for G may be larger, but can be reduced again by incurring another factor of $1 + \frac{\delta}{n}$. Since graphs are combined at most n times, the total factor incurred is at most $(1 + \frac{\delta}{n})^n \approx 1 + \delta$. □

Note that the special case where the series-parallel graph is a single path is the same as knapsack [11] and thus NP-complete.

The case where the collection of paths P is given explicitly and does not contain all paths is harder.

Theorem 8 *For a given collection of paths P for G, with intervals $[l_e, h_e]$ given by $[0,0]$, $[0,1]$ or $[1,1]$, the unique-upper-length case is as hard to approximate as $(\kappa+1)$-hypergraph vertex cover even if $\kappa = K - 1$. With arbitrary intervals $[l_e, h_e]$, the problem has an $(\kappa+1)$-approximation algorithm.*

Proof Sketch: Let R be an instance of $(\kappa+1)$-hypergraph vertex cover consisting of n vertices, and hyperedges each having $\kappa + 1$ vertices. Construct a DAG consisting of a path of length n, where each edge is replaced by two parallel edges with intervals $[0, 1]$ and $[1, 1]$. (Use an additional edge with interval $[0, 0]$ if parallel edges are not allowed.) Each edge on the path of length n corresponds to a vertex of the hypergraph. We choose a path for each hyperedge, selecting the edges $[0, 1]$ corresponding to the vertices in the hyperedge, otherwise selecting

the edges $[1,1]$. A solution must query at least one edge in each such path, and thus corresponds to a vertex cover in the hypergraph.

The $(\kappa+1)$-approximation algorithm is obtained again by the linear programming relaxation. We introduce a variable $0 \le x_e \le h_e - l_e$ for each edge e. The idea is that $x_e = 0$ if e is queried and $x_e = h_e - l_e$ if e is not queried. Write $\sum_{e \in p} x_e \le \kappa$ for each path p in P. The objective function to be minimized is $\sum_e w_e(1 - \frac{x_e}{h_e - l_e})$. Let w be the value of the optimum. If we query all edges for which $1 - \frac{x_e}{h_e - l_e} \ge \frac{1}{\kappa+1}$, we incur cost at most $(\kappa+1)w$. For each edge e in p not queried we have $1 - \frac{x_e}{h_e - l_e} < \frac{1}{\kappa+1}$, or $h_e - l_e < \frac{\kappa+1}{\kappa} x_e$. Therefore the sum of the lengths $h_e - l_e$ of intervals over edges e in p not queried is at most κ. □

4 The General Case

We now consider the case of arbitrary $\kappa \ge 0$ and arbitrary intervals $[l_e, h_e]$.

Proposition 4 *A choice of queried edges guarantees error κ if and only if for each path p in P there is a path q in P (possibly $q = p$) such that $H - L + x \le \kappa$. Here H is the sum of h_e over edges e in q and not in p, L is the sum of l_e over edges e in p and not in q, and x is the sum of the interval lengths $h_e - l_e$ over edges e in both p and q that are not queried. (The general case is thus in Σ_2.)*

Proof Sketch: Suppose there is a path p such that $H - L + x > \kappa$ for each path q. Answer the queries to edges e in p by l_e, and answer the queries to all other edges f by h_e. Let L_0 be the minimum possible length on p. Then for every path q, the maximum possible length is at least $L_0 + (H - L) + x > L_0 + \kappa$.

Suppose for every path p there is a path q such that $H - L + x \le \kappa$. After the queries, the minimum possible length of a shortest path is the minimum possible length L_0 for some p. The maximum possible length for the corresponding q is at most $L_0 + (H - L) + x \le L_0 + \kappa$. □

Theorem 9 *If each path in P contains at most r nontrivial edges, then the problem is as easy and as hard to approximate as r-hypergraph vertex cover, for $r = O(\log n)$; in particular, it has an r-approximation algorithm.*

Proof Sketch: The hardness was shown in Theorem 8 with $r = \kappa + 1$. For the easiness, consider each path p. For a choice of edges X to be queried in p, we can determine whether $H - L + x > \kappa$ for each path q as in Proposition 4. If this is the case, then at least some nontrivial edge in p not in X must be queried, giving a set of at most r nontrivial edges to be covered, and thus defining a corresponding hyperedge of size at most r. The number of choices X to be considered for p is at most 2^r, thus polynomial in n. □

Theorem 10 *If the nontrivial edges of G have r colors, so that the nontrivial edges in each path p from P have distinct colors, then the problem is as easy and as hard to approximate as r-partite hypergraph vertex cover, for $r = O(\log n)$; in particular, it has an $\frac{r}{2}$-approximation algorithm [9, 5].*

Proof Sketch: Let R be an instance of r-partite hypergraph vertex cover, with r parts R_i. Construct a DAG consisting of a path of length r, where the ith edge is replaced by $|R_i|$ parallel edges with intervals $[0,1]$ of color i. Each hyperedge in R thus corresponds to a path in the DAG since it selects an element from R_i for each i. Setting $\kappa = r-1$ forces each hyperedge to be covered, proving the hardness.

The easiness is as in Theorem 9. The hyperedges correspond to the nontrivial edges in p not in X for some X, so they all have elements of different colors, i.e., elements in different parts R_i of they r-partite hypergraph. □

Corollary 1 *If P consists of all paths in G, and each such path has at most r nontrivial edges, then the problem has an $\frac{r}{2}$-approximation algorithm, if r is constant. In particular, the case $r = 2$ can be solved exactly. (The case $r = 3$ is NP-hard to approximate within $1+\delta$ for some $\delta > 0$.)*

Proof Sketch: Assign to each nontrivial edge e a color i which is the maximum i such that e occurs as the ith nontrivial edge in a path p. There are at most r colors, and all the nontrivial edges in each path p have different colors. The choice of at most r nontrivial edges for a path p can be assumed to determine p, since we can choose the remaining trivial edges so as to minimize the length of the path. Thus the number of paths to be considered is $O(m^r)$.

The hardness for $r = 3$ was established in Theorem 5. □

A *bi-tree* is a series-parallel graph consisting of a tree S with root s, edges oriented down from the root, a tree T with root t, edges oriented up to the root, where the leaves of S coincide with the leaves of T.

Theorem 11 *Bi-trees have a $(1+\delta)$-approximation algorithm for all $\delta > 0$, and an exact polynomial time algorithm if κ is bounded by a polynomial.*

Proof Sketch: Consider the optimal solution. Consider a series-parallel subgraph G' of the given bi-tree which is given by a subtree rooted at some s' of the tree rooted at s, and a subtree rooted at some t' of the tree rooted at t. The paths p going through G' such that the corresponding q satisfying Proposition 4 does not go through G' are determined by a lower bound L_0 on the sum of l_e over the edges e of p in G'. Thus, there are at most n different scenarios for which paths p going through G' must have their corresponding q going through G' as well. If the set of such p is nonempty, then the sum x_0 of the $h_e - l_e$ for edges from s to s' or from t' to t not queried must satisfy $x_0 \leq \kappa$, for a total of κn scenarios for each such G'.

Each such G' is obtained by combining two G'_1, G'_2 in parallel, or by taking a G'_1 having some s'_1, t'_1 as source and sink, and adding either an edge (s', s'_1) or an edge (t'_1, t'). The optimal solution for each scenario for G can be obtained from the optimal solution for the scenarios for G'_1 for this last case or for the scenarios for both G'_1, G'_2 in the previous case, because given x_0 it is easy to determine which paths q in G'_1 take care of paths p in G'_2 and vice versa.

For large κ, we proceed as in Theorem 7 and introduce at each step an approximation factor of $1 + \frac{\delta}{n}$, so that the total factor incurred is at most $(1 + \frac{\delta}{n})^n \approx 1 + \delta$. □

Note that the special case where the bi-tree is a single path is the same as knapsack [11] and thus NP-complete.

Theorem 12 *If P consists of all paths in G, and G is made up of components G_i in series, where each G_i has an α-approximation algorithm, then G has an $\alpha(1+\delta)$-approximation algorithm for all $\delta > 0$, and an α-approximation algorithm if κ is bounded by a polynomial.*

Proof Sketch: A solution must combine κ_i for each G_i that add up to at most κ. We proceed inductively for the possible values of partial sums $\kappa_1 + \cdots + \kappa_i$, and combine solutions accordingly.

For large κ, we proceed again as in Theorem 7 and introduce at each step an approximation factor of $1 + \frac{\delta}{n}$, so that the total factor incurred is at most $(1 + \frac{\delta}{n})^n \approx 1 + \delta$. □
